PREFACE

Today, almost seven billion of us live side by side with whales and woodlands because we get almost all of the energy we use from oil, coal, and natural gas. If we suddenly quit using these fossil fuels and returned to burning whale oil and wood, we wouldn't come close to powering enough of our tractors, trucks, and irrigation pumps to feed us all.

The good we get from fossil fuels is a mixed blessing, though. If we keep using them, and accept the risks of oil-well blowouts and mountaintop removal, for long enough, the fossil fuels will run out—we are burning them about a million times faster than nature saved them for us. We thus must decide whether to burn most of the fossil fuels and then look for replacements, or to learn while we burn and while we still have a fossil-fuel safety net in the ground.

Our decision must be made under the shadow of global warming from the CO₂ released by burning fossil fuels. Sensors on heat-seeking missiles are affected by the interaction between CO₂ and energy transfer through the air, and so is the climate. The atmosphere really doesn't care whether we study it for warring or warming, and military as well as civilian physics research shows that CO₂ matters. We thus have high scientific confidence that continuing to burn fossil fuels will cause large climate changes, which will make life more difficult for poor people living in hot places now, and for most people in future generations.

But if CO₂ emissions especially harm poor people, are we wiser to reduce emissions, or to reduce poverty by helping people become wealthier? Not surprisingly, economics answers “Yes”—do some of each. How much of each may depend on national security, jobs, ethics, and insurance, as well as economics.

You will hear a lot of shouting from the wings that partially drowns out discussion of these important issues, but this shouting is nothing new. President Abraham Lincoln's administration found ways to get good scientific advice through the noise, and following his example still works. I will try to stick closely to Lincoln's example in giving you the best scientific insights. There are things that science doesn't know, more things that I don't know, and I am far from infallible, but much of the science really is solid, and I will tell you when it isn't.

Lincoln also showed us part of the solution for powering the planet. Earth offers vast, sustainable energy resources with the potential to improve the economy and generate a lot of fortunes, including the wind that so intrigued Lincoln on the Illinois prairie long before his presidency.

Being a truly honest broker on such complex topics may be impossible, but I will do my best for you. This could be easier for me than for most people: I enjoyed working for an oil company and benefited from its largesse, my political registration is right of center, and I have won scientific awards for helping show just how bizarrely Earth's climate can behave without any interference from us. But I also helped the U.S. National Academy of Sciences and played a small role in the Nobel Prize-winning effort of the United Nations Intergovernmental Panel on Climate Change (IPCC) where my knowledge of Earth's history and behavior contributed to the confident realization that the CO₂ from our fossil-fuel burning is highly likely to change the world in fundamental ways that will increasingly make life harder for future generations. Our two lovely daughters give me a personal as well as a professional stake in the search for a stable, sustainable world. Onward!

PART I.

THE BURNING QUESTION

Prepare to Come About

Synopsis. We humans have always used energy and always will. We now rely greatly on fossil fuels, which promise to make our lives much harder before they run out. But there are plenty of ways to get rich and save the world by remaking our energy system.

May you live in interesting times. —Old curse¹

Power On

More and more of us are living better than ever before. In most of the world, an expectant mother can be reasonably confident that she will deliver a healthy baby, who will parent the next generation and live long enough to help educate the generation after that. Wars continue, but the all-out disaster of World War II is ancient history for many of us, and a fading memory for the rest. We have used our accumulated knowledge and wisdom, and the things we've built, to convert a world that might support a few million hunter-gatherers² into home for over six billion of us, heading for nine or ten billion. When problems arise, we usually invent and cooperate to solve them. We have never fully agreed on the purpose of our existence (and we are not likely to agree in the near future), but if we approve any form of "The greatest good for the greatest number," then this really may be the best time in history.

And yet, we can easily believe we are cursed to live in these interesting times, with disaster waiting at every turn. Perhaps a billion or more people—one in six of us—exist in such poverty and violence that they cannot reasonably expect their children to live long and prosper. Various accounting methods suggest that we are using, and often using up, nearly half of everything that the planet makes available to us and to all other species, with rising population and expectations pushing us rapidly toward using 100 percent.

We have removed perhaps 90 percent of the large fish from the ocean; in fact, we have no idea what a natural ocean ecosystem looks like, because we fished out so many species before scientists learned to see what is going on.³ Roughly one-third of the land surface not covered by ice sheets is now used for cropland or grazing, with logging extending our impact.⁴ Water is essential to us, but in many places a large fraction of the water we use is not being replaced, as we pump it out of old deposits in the ground or melt it from old deposits in glaciers much faster than new rainfall or snowfall supply more.⁵ The soil that grows our crops is being washed away far faster than nature can produce more,⁶ so farming is becoming more difficult, especially as we use up the "easy" deposits of phosphate for fertilizer.

With human population expected to increase, many of us not getting even the minimum that

most civilized people believe is needed for a proper life, and almost everyone hoping to improve the lot, it takes an optimist to believe that the demands on the planet will “only” double. If our use already approaching half of everything supplied by Earth, where will the rest come from? And what does our growing use mean for the other species that share the planet with us, and their ecosystems on which we rely?

A pessimist can easily look past our successes in advancing knowledge and skills and building infrastructure and healthy people, and see the history of disasters, wars, environmental refugees, starvation, and failure.⁷ Humanity has had more than enough “wins” to show that success is possible but more than enough failures to show that success is far from guaranteed.

If water runs out, we can desalinate and pump. If soil runs out, we can grow crops hydroponically without soil, or we might dig the dirt out of the reservoirs behind dams and spread it back on the fields while adding key nutrients, much as a home gardener builds raised beds. If phosphate becomes scarce, we can mine lower-grade ores and use our knowledge of chemistry to enhance them.

But desalination uses energy, and lots of it. So does building a hydroponic system, and mining low-grade ore. So do plowing and shipping, heating and cooling, flying and driving, and so many other things we do. We already rely heavily on energy use to solve our problems: powering pumps to pump water out of the ground to grow our crops, fueling huge shovels to dig phosphate and ships to send it—often great distances—to the farm fields, where fuel-filled tractors spread it, and much more. And our energy use is arguably the most unsustainable part of our lives.⁸ Roughly 85 percent⁹ of the world’s primary-energy production today is from fossil fuels—oil, coal, and natural gas—with only 15 percent from nuclear, hydropower, wind, or other sources. We are using the fossil fuels approximately a million times faster than nature saved them for us, and they will run out (see chapter 4).

We apply cheap energy to almost all of our problems, a “silver bullet” to slay the dragons that trouble us. But if we continue on our present course, we will run out of silver bullets. Our current energy system cannot last. Worse, the by-products of that energy system threaten to change the planet in ways that will make our lives much harder—if we burn all of the fossil fuels before we learn how to use new energy sources, we will have greatly increased the difficulty of our education.

Fortunately, we have a golden bullet in our pocket—our collective cleverness. The amount of energy that Earth makes available, sustainably, dwarfs the amount that we now use, and dwarfs our demand for the foreseeable future. Sunshine from just the desert floors of Arizona would power the whole United States, and from the Sahara could power the rest of the world’s people, with huge amounts left over. The technologies required are not science fiction—in fact, they already exist or soon will, and some of them are decades or centuries old.

But big projects take a long time to complete. In 1971, the then U.S. president Richard Nixon declared war on cancer. He proclaimed, “The time has come in America when the same kind of concentrated effort that split the atom and took man to the moon should be turned toward conquering this dread disease. Let us make a total national commitment to achieve this goal.”¹⁰ Almost forty years later, although the goal remains elusive, huge progress has been made. But the first decade or two of this “war” did not produce the heady victories we hoped for. Very simply, cancer proved to be a hard problem.

Figure 1.1 Karen Alley sailing: “Prepare to come about.”

I believe that our energy problem will prove easier to conquer than cancer, as I discuss in part I of this book. But the effort required is easy to underestimate. Our oil and coal companies are so good at what they do that we easily forget the sheer immensity of their achievements. We occasionally are reminded of the near impossibility of quickly containing the oil from even one spill when an oil well blows out or a supertanker runs aground in an ecologically sensitive area, but drill rigs and tankers are at work continuously. The efficiency with which some coal-mining companies change the very face of Earth—removing the tops of mountains, filling valleys with the non-burnable rocks, and moving on—to extract the energy stored beneath is mind-boggling.

Changing the direction of an oil tanker, or any large ship, is a slow process. By the time the pilot sees an obstacle ahead, mutters, “Oh, (very bad word),” and tries to make a correction, a collision may be unavoidable. The inquiry into the sinking of the Titanic revealed that when the crew sighted the iceberg, it was already too late to steer to safety: “We had the order, ‘Hard-a-starboard,’ and she just swung about two points when she struck.”¹¹

A remarkably wide range of thinkers, scientists, and engineers now see the ship of our energy use on a collision course that will seriously harm our future, unless a correction is begun soon. The change is still possible—we are not the Titanic, doomed to hit and sink—but the longer we wait, the harder the change will be, and the more damage we will do as we sideswipe the unpleasant reality. As my younger daughter Karen says to her crew when sailing her Sunfish in much more pleasant times: “Prepare to come about.”

THE OPERATORS’ MANUAL

*When all else fails, read the operators’ manual.*¹²

I routinely board very large airplanes without having the vaguest idea of how they work or how to fly them—I’m a passenger, and happy to ride along. I take buses, and taxis, and ride shotgun when other people drive, without sweating it. But put me behind the wheel of the car, and I suddenly need to know

whole lot more. Manual or automatic? Mirrors adjusted right? Where is the knob for the headlight? Emergency brake, just in case? When I buy a new car, I actually do skim over the manual. And when the brakes went out on the geology van coming down the mountainside during my student days, knowing what to do was a distinct comfort in a tight spot.

I'm educated as a geologist, with climate and ice and water and a bunch of engineering thrown in. I have been an academic most of my professional life, but I worked for an oil company for a while and enjoyed both the money and the smart people doing interesting things there. My experience was similar to that of many geologists, who for more than a century have been getting good jobs to help people find valuable things in the Earth (oil, coal, diamonds, gold). Geologists also get jobs to help people avoid hazards (volcano! landslide!), and to be entertaining (dinosaurs!). Recently, however, we have been asked to take on another job.

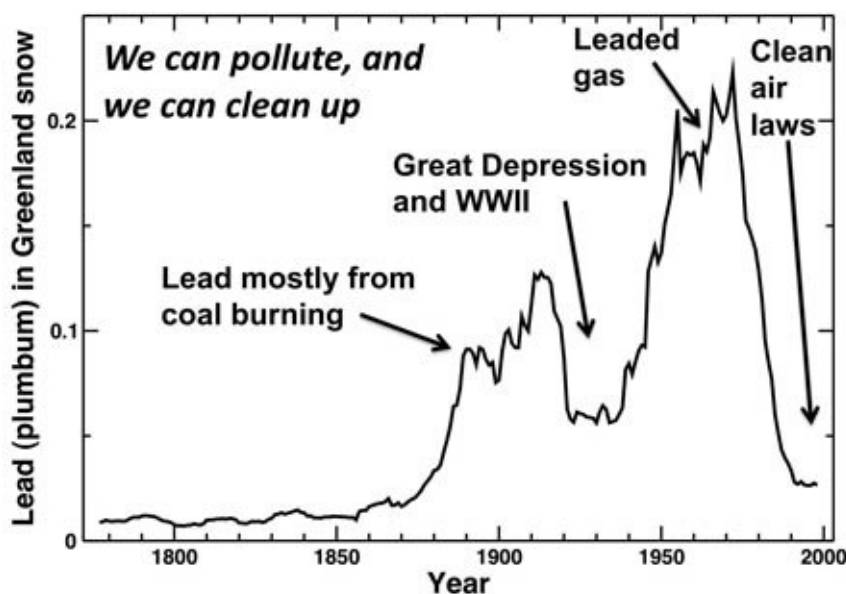

Figure 1.2 Final assembly of the drill and protective dome for deep ice coring at GISP2 in central Greenland. Records from ice cores tell us the history of the atmosphere, including natural and human-caused changes.

I often have taught geomorphology, the science of why Earth's surface looks the way it does, and the task has been getting harder. More and more, the processes that made Earth's landscape in the past are not the processes that students observe today, because the dominant processes today are "us." We now move more rocks and dirt than nature does—all of the natural landsliding of hillsides and mud washing down rivers and dust blowing through the air are small compared to the work of o

bulldozers and steam shovels.¹³ Many home gardeners in suburbia are convinced that they have poor soil, and most of them are right—builders often dig a hole for a foundation and perhaps a basement, spread the rock and clay to smooth the lot, throw a bit of “topsoil” on just thick enough to grow grass and call it a job well done. Digging a hole for a tomato plant then means tapping into a mess of whatever came out to make room for the foundation or basement, plus some nails and shingle pieces and other construction debris. A geomorphology student wanting to learn about nearby natural soils may have difficulty, because most of the easy-to-visit soils have been so greatly disturbed by humans.

A reporter called recently and asked how long it would take Earth to “forget” humanity if we suddenly disappeared. In some sense, we are now unforgettable—the human-caused plant and animal extinctions have emptied biological “jobs” that will be filled over many millions of years by creatures who will owe their existence to us wiping out the competition. We have pumped oil and gas out of the ground that had been there for hundreds of millions of years, through holes that may not be eroded away for additional hundreds of millions of years. The human “layer” of plastic and aluminum foil and heavy metals may be recognizable in sedimentary piles hundreds of millions of years from now.

[Figure 1.3](#) Recent history of concentration of lead pollution in Greenland snow.

In Greenland, I helped collect ice cores to learn the history of the atmosphere. The folks who study the trace chemicals in the ice can see the clear signal of mining of lead—*plumbum*—used to supply the plumbing of the Roman Empire. The post-Roman drop in lead level is followed by a rise beginning with the Industrial Revolution, a drop for the Great Depression, a huge rise with the use of leaded gasoline and paint after World War II, and then a great drop when we became concerned about lead poisoning and got serious about cleaning up.¹⁴ The lead will be in the ice for a long time if we don’t melt it out, and our lead will persist in the muds of lakes and the sea floor even if we do melt the ice.

With the amount of stuff we use, and the amount of the world we occupy, we are no longer passengers napping in the back seat of the car. We are everywhere, and changing everything. Hence many environmental scientists are now involved in figuring out what we are doing, how to operate

remarkably complex and involved Earth system, and how to make the ride as enjoyable as possible. ~~This operators' manual is not finished yet—not even close—although we know an amazing amount~~ more than we did even a few years ago, with knowledge coming in rapidly. I am proud to have played a small part in this effort. But I'm also concerned that a lot of people, including some of those who are making laws, still think that they are sitting in the back of the car, looking out the window and enjoying the ride.

I can't possibly cover all of what we know about how the Earth system operates in this one book. Instead, I will focus on a few big ideas: 1) we humans have always used energy and always will, 2) the road we're on now will get us into trouble, and 3) there are plenty of ways to get rich and save the world by remaking our energy system. Along the way, we'll look in on some amazing moments in Earth's history, visit a few of our ancestors, and check in on some fortunes in the making.

Burning to Learn

Synopsis. Humans burn things, and burning was probably required to make us human. Despite many problems, burning has helped us, and the more we have burned, the better off we have been in the past.

The mind is not a vessel to be filled but a fire to be kindled. —Plutarch¹

BRAIN POWER

Have you figured out how to get someone or something else to do most of your work for you?

If you answered yes, congratulations! You're human!

Many things set us apart from most of the other creatures on our planet. Text-messaging and tool-making are a lot easier with an opposable thumb. Baldness is not just about looking distinguished (said the rapidly balding man . . .)—lack of hair over large expanses of our bodies lets us run marathons without overheating, a useful ability for a hunter-gatherer chasing a meal or trying not to become dinner for a pursuing jungle cat. Upright posture lets us wear ties to business meetings, but also lets us see what we're chasing or what is chasing us, and lets us throw rocks or swing clubs at predators or carry our tools and tots to the next meal. Our big brains allow us to develop language and agriculture better than any other creatures on the planet.

But how do we afford those big brains? When we are resting, 25 percent of our energy use goes to the brain, compared to just 8 percent averaged across the apes.² A resting newborn baby's brain accounts for a whopping 60 percent of energy use. Our brains, like older desktop computers, use a lot of energy even when idling.

How did our ancestors find the energy for their on-board computer power? One way is that evolutionarily, they skimped on stomachs.

Hay for dinner, anyone? A cow can do it, but it takes four stomachs and a lot of chewing the cud in the evening. Much of the energy the cow gets from the grass goes to keeping those stomachs alive and working, and keeping the cow alive and chewing to aid in the digestion.

Figure 2.1 Cows can be curious creatures, as demonstrated by these Penn State Holsteins investigating the filming of *Earth—The Operators' Manual*. But cows are not the brightest lights in the intellectual firmament, with more stomach than brains, at least in part because of the difficulty of digesting their diet.

Our closer relatives, such as chimpanzees, eat a variety of things, and have relatively longer guts than we do. A chimp can successfully digest foods such as leaves that would pass almost unaltered through me. But some of the energy the chimp gets from digesting that food is used to keep the chimp's gut alive to do the digesting, leaving less to power the chimp's brain or other parts of the body. Adding a longer gut would allow more digestion, but with diminishing returns as that longer gut used more energy itself.

Therefore, someone with a shorter gut, with fewer gut cells to keep alive, can divert the energy those cells would have used to power their brain. But a gut that is too short would allow undigested food to be dumped out the rear end, wasting energy, so a shorter gut saves energy only if it is supplied with a more-digestible dinner.

Meat-eating is one solution. Let some other creature do the hard work of collecting and chewing and digesting vegetables and reassembling their parts into something more useful to an animal, and then eat that other creature. Our ancestors were clearly using tools and eating meat more than 2 million years ago, and their brain sizes increased between about 1.9 and 1.6 million years ago, when there is increasing evidence of increasing meat-eating.³

A fascinating new hypothesis links our very humanity to another way of improving digestibility: cooking. If our ancestors used fire to start digesting food outside their bodies, a shorter gut inside could finish up the job, allowing them to be well fed and smart at the same time.⁴

We know surprisingly little about the advantages of cooking, considering how much cooking we do, but recent research points to an important role for cooking in improving digestibility as well as killing diseases.⁵ In one experiment, mice that were fed cooked meat gained almost one-third more weight than those eating raw meat. In another study, switching pythons from a raw-hamburger diet to a cooked-hamburger diet reduced the energy they used to digest their dinners by almost one-fourth. Furthermore, people eating primarily raw foods tend to lose weight. Some paleoanthropologists have

speculated that cooking was a prerequisite for our spurt of brain growth beginning 1.9 million years ago, although evidence of organized, consistent fire use at that time remains sparse at best; perhaps more likely, fire contributed to the next big spurt of brain growth, within the last half-million years, leading to the large size of our brains today.

Figure 2.2 Native American fire circle, Wind River Mountains, Wyoming. A skilled cook could use this to prepare food efficiently, conserving firewood, but the energy used in cooking was similar to the energy available to people in the cooked food.

Cooking thus looks like a great deal for people. Burn some trees, use the heat released to make the food more digestible, and we get lots of energy from the food with a small investment supporting our guts. The extra energy powers our minds, and we're human.

But what does this mean for the trees? Perhaps 10 percent or less of the heat from an open cooking fire actually warms the food.⁶ When I was on a field expedition to study the ice-age deposits of glaciers of the Wind River Range in Wyoming, the archaeologist Dave Putnam showed us neat, small, efficient stone circles that native Americans had used, probably about 10,000 years ago. Carefully tended, fires in such fire rings might have achieved 20 percent efficiency or more, much closer to the efficiency of a modern stove. If you cooked grain on such an efficient fire ring, the energy you obtained from eating dinner might be slightly more than the energy used in cooking dinner.⁷ For a sloppy fire, you might use twice as much energy in cooking as you obtain from eating the cooked food. (Don't even think about how inefficient cooking a marshmallow over a campground fire is.) And most of the energy from our food goes to the body, with only a little bit of the extra energy making our big brains possible. So, a lot of trees had to give their lives, and a lot of termites were deprived of their dead-wood dinner, to make us smart.

Some of the science discussed here is new, and research is ongoing. But it appears that being human means relying on energy from outside—we learn because we burn. And our reliance on the energy of others, and the difficulty of supplying that energy from our traditional sources for billions of people, are daunting indeed.

WHAT IS ENERGY, ANYWAY?

We can usefully divide the universe into two categories: stuff, and the ability to make the stuff do something. You might call these “matter” and “energy.” Albert Einstein is famous in part because he showed that matter, or mass, and energy are really the same thing—wind up an old-style alarm clock and you have made the spring a tiny, tiny, tiny bit more massive, and the extra mass will be turned into energy to move the clock’s hands and make the ticktocks over the next day.⁸ Blow up an atomic bomb and although you would have difficulty measuring the amount of mass lost, you will easily see the energetic effects of that loss. For most ordinary purposes, though, it is sufficient to treat mass and energy separately.

If you put the right chemicals together in the right pattern, you can make a diamond that looks pretty and scratches things really well, or a hammer that can break things. Use the hammer to break the diamond into tiny bits, toss the dust out the window, and the diamond is no longer useful to you. The stuff is still there—mass is conserved, as the physicists say—but you have to gather the mass the right way to make it valuable.

Energy is much the same. If you store a lot of energy where you want it, you can use it to make the stuff do what you want. Put a lot of heat energy in a small place, and you can cook a turkey. Or you can let the heat drive the expansion of gases to drive a piston to drive a car to drive you across the country to visit grandma for a turkey dinner. When you are done, the energy is not gone, but it is spread out—you heated the room while cooking the turkey, and then the heat from the warmer room spread out into the outdoors and eventually was radiated to space. Once the heat energy is too spread out, you can’t use it. Just like the dust from your broken diamond, the energy exists but it isn’t valuable any more.

MEASURING THE BURN

Comparing the energy used in a cooking fire to the energy contained in the cooked foods is easier if we can put numbers on the energy amounts. But how do we measure energy? One way is to use our dining habits.

The U.S. Food and Drug Administration (FDA) suggests appropriate foods and nutrients that we should eat. These FDA recommendations are often given assuming a diet of 2000 calories per day. “Calorie” is a measure of the energy available, and “calories per day” is the rate at which you use the stored energy, converting it to spread-out heat. How rapidly you use stored energy is also called “power”—your personal power output is 2000 calories per day.⁹

Most other branches of modern science, and nonscientists in most other countries, don’t measure energy storage in calories, but in joules (named after an English physicist who started out as a brewer and who experimented with electricity in part by shocking his brother and letting his brother shock him.)¹⁰ The scientists who use joules for energy storage also use watts for power (abbreviated W, and named after James Watt, a Scottish inventor of steam-engine fame, who according to his epitaph “enlarged the resources of his Country, increased the power of Man, and rose to an eminent place among the most illustrious followers of science and the real benefactors of the World”).¹¹

If you follow the FDA guidelines and burn 2000 calories per day inside of you, your personal power output averages 100 W. Not that long ago, when almost all of us lit our houses with heat-untill-they-glow incandescent lightbulbs, everyone understood what watts are—a big turned-on lightbulb

was using 100 W. (With modern compact fluorescents, 100 W is four or five bright lightbulbs.)¹² you ever touched a 100 W incandescent lightbulb that had been on for a while, you know that it was hot! So you shouldn't be surprised that you and the lightbulb are using energy at about the same rate. You may use 150 or even 200 W during part of the day, then idle down while sleeping, but your average will be in the neighborhood of 100 W. A Tour de France bicycle racer may eat 10,000 calories per day, to average a power output of 500 W. A whole lot of that energy goes into waste heat, but at the very highest level for a human, an elite bicycle racer may put close to 500 W into moving the bicycle up a mountain stage. The rest of us can only dream about that, so when we consider amounts of energy, just remember that the energy each of us generates is 100 W.¹³

Recently, total energy usage in the United States has been running notably higher than the personal burning inside of us. In fact, the total energy use in the United States in a day, divided by the number of people, gives approximately 240,000 calories per person per day, or somewhat more than 10,000 W for each person.¹⁴ This is the equivalent of each of us having more than 100 people doing our bidding—100 energy “servants” apiece. We are really better off than that, though. If each of us actually had 100 people to do our bidding, we wouldn't get this much work out of them, because most of their time and most of their energy would be used to keep themselves fed and clothed and toileted and otherwise alive.

Some people become discouraged when they think about the huge energy and environmental challenges facing us. Giving up is wrong, though. If you start to get discouraged, just remember that Abraham Lincoln ran his mind and body on the same amount of energy as a single heat-until-it-glow lightbulb. You, and Einstein, and Beethoven, and Michelangelo, taken together, use or used less energy than a single chandelier. The careful mathematics of science yield the same answer that we teachers learn from our students—we have more than enough brainpower to figure out how to power our brains!

BURNING TO EARN

Richer countries, and richer people, use more energy.¹⁵ And using the energy helps the people. (I will come back to the problems from the energy use later, and there really are problems, but the good from energy use still outweighs the bad.)

Across the countries of the world, those that use more energy per person generate more economic activity per person. There are notable variations, with countries such as Russia, Saudi Arabia, and Canada using more energy to make a dollar (or a euro or a ruble) of economic activity than countries such as Japan, Italy, and the United Kingdom. These differences matter, but they are not huge, with the less efficient countries usually using no more than about twice as much energy per dollar as the more efficient countries. We all know that the correlation between energy use and economic activity does not necessarily tell us that using energy helps the economy. The world economy has grown over the same time that my hair has fallen out, but the extra sunscreen I buy to cover my expanding forehead during soccer games is not economically significant globally, so my spreading baldness is not responsible for the rising wealth of nations. But overall, we know that the wealthy use more energy, and serious thinkers typically find that the good things obtained from the energy help create the wealth.

Suppose that I keel over from a heart attack while sitting at my computer. My neighbor will use a phone powered by electricity to call a hospital, which will dispatch an ambulance powered by

gasoline. A machine powered by electricity might keep me breathing and keep my heart beating until a doctor can fix the problem. The knowledge and dedication of my neighbors are essential to save my life, but so are the machines and the energy they use. My recovery would be aided by the plentiful food in the climate-controlled hospital, with the air-conditioning or heating, the food refrigeration and cooking and trucking, the plowing and planting and fertilizing, all relying on energy sources that go far beyond the 2000 calories per day that I actually eat.

In an economic sense, the wealthy are not using more energy because they are wasteful.¹⁶ In general, the wealthier you are, the more dollars of economic activity you get from a given amount of energy. As an example, in the United States from 1973 to 2008, economic activity (the gross domestic product, with the effects of inflation removed) more than doubled, while energy use increased by only one-third. Thus, the people of the United States in 1973 used slightly more than twice as much energy to earn a dollar as the people in 2008. The effects of inflation have been removed, so energy efficiency really went up. But energy use still rose, because the economy grew even faster than energy efficiency grew.

There are lots of ways to “spin” these sorts of data in public discourse, and you should have no difficulty finding people spinning this discussion many different ways. Because the wealthy generate more dollars of economic activity per barrel of oil, you could argue that the wealthy are more efficient than the poor. Because the wealthy use much more energy, and much more stuff per person than the poor, you could argue that the wealthy are much less efficient. Both are correct in some sense. The best interpretation of the data probably is: 1) energy use helps increase wealth, which increases energy use; 2) the wealthy energy users find ways to improve efficiency; but 3) the effects of item 2 are not large enough to offset the effects of item 1.

I will come back to facts and figures later. But first, to explore the role of energy in our lives, the ways we have gotten it, the costs and benefits, let's first look at some of the history of our energy use. I will tell you a few stories that interest me, without in any way subjecting you to a comprehensive treatise.

Peak Trees and Peak Whale Oil

Synopsis. Our ancestors moved to new energy sources in part because the old sources were running out. Much of the natural world we enjoy now owes its survival to our use of fossil fuels instead. We cannot go back to our old ways as the fossil fuels are exhausted.

*A king's head is solemnly oiled at his coronation, even as a head of salad. . .
. Think of that, ye loyal Britons! We whalemens supply your kings and queens
with coronation stuff! —Herman Melville¹*

The Sinking Rock

One of the many attractions of the Cape Cod National Seashore, in Eastham, Massachusetts, near the old Coast Guard station, is a giant boulder that was delivered long ago by ice-age glaciers (see chapter 11). Climbing to the top of Doane Rock is a rite of passage for youngsters—if you can scramble all the way up and back down safely by yourself, you're a big person. My wife's family has been visiting the region for over a century, and those good people have been kind enough to include me over the last few decades. My father-in-law, Niel Richardson, likes to joke that Doane Rock has been sinking. When he was a lad during the 1930s, he would sit atop the rock and watch the waves breaking on the beach, half a mile away. Now, the pitch pine and scrub oak are much taller than the rock, and a kid perched on top can barely see Doane Road, 100 feet (30 m) away.

Of course, Niel knows that sinking has nothing to do with it—instead, the trees grew. The Cape Cod that the Pilgrims found in November of 1620 was “so goodly a Land, and wooded to the brinke of the sea.”² The Pilgrims, and those who followed them, then set about deforesting the Cape. Building ships and homes consumed many of the best trees. The 1700s-era Doane House, where we sometimes stay, has irregular-width oak boards in the floor, including some of such remarkable size that nothing similar could be made from Cape trees today.

[Figure 3.1](#) *Doane Rock, Cape Cod National Seashore, was deposited by a glacier during the ice age and is the largest such “erratic” boulder on the Cape.*

Early New Englanders didn’t need ocean-going boats for whaling; they could launch small boats from the shore, especially to hunt right whales (possibly so-named because they are the “right whale” to hunt, since they swim close to shore where they can be killed, and they float after being killed). Shore whaling may have begun as early as the 1620s off Cape Cod, and was economically important during the latter 1600s and into the 1700s. Boiling the blubber in the “try works” to extract the valuable oil was started by burning wood for heat, although the cooked-out whale pieces could later be added to fuel the fire, giving a reportedly strong and very unpleasant odor.

[Figure 3.2](#) *The view from Doane Rock. In the early twentieth century, this photo would have showed a treeless plain sloping*

The howling winter winds on Cape Cod can be bone-cutting cold, so the fireplace in the Doane House, and similar fireplaces in houses up and down the Cape, provided a welcome relief for the people. But the fireplace burned wood—perhaps an acre of trees (0.4 hectare) per year for a house³ which came from the rapidly dwindling forest. In 1690, the town of Eastham, home of Doane Rock, enacted a rule to prevent logging on the common lands except for export to make money. This was extended to all lands in 1694, and even export logging was banned in 1695, but the trees seem to have been gone by 1700.⁴ The Cape was almost completely deforested, and then kept bare into the early 1900s, when fossil-fuel burning became important and the demand for trees dropped. My father-in-law grew up with the returning forest of the Cape, a forest that really owes its existence to fossil fuels.

Very simply, the land of the Cape was capable of growing lots of trees that were big enough to use for construction as well as fuel, but the human demand between the 1600s and about 1900 far outstripped the ability of the land to grow those trees; rising use of fossil fuels eventually reduced the demand for Cape Cod trees so greatly that they are now growing back, blocking Niel's view of the ocean from the great rock but providing a beautiful cover to the Cape, which is allowing wildlife to return and eroded soils to re-form. Before the Civil War, scarcely more than 30,000 people kept the Cape nearly treeless; 150 years later, 200,000 more people live on a tree-covered Cape.⁶ The difference? Fossil fuels.

THE GREAT PENNSYLVANIA DESERT

I live in Pennsylvania—Penn's Woods. I am fortunate to teach at a great university, Penn State. After class, our students walk off campus into a town that is younger than the university. The university was founded in 1855 far from any city, up the hill from an iron furnace. That furnace still guards the main road out of town. Of the thousands of people who pass each day, I suspect few even notice the furnace and fewer realize that they are there because of the furnace.

Much of the infrastructure of the U.S. East Coast in the early 1800s was built of Juniata iron, which was mined, smelted, and forged in and near the valley of the Juniata River in central Pennsylvania. Beginning in the late 1700s, entrepreneurs converted the rusty soils of the region into pig iron, which was then forged into other useful items. Place names such as Pennsylvania Furnace, Lucy Furnace, Harmony Forge, and the older and more easterly Valley Forge of Revolutionary War fame testify to the influence of the iron industry. Iron-making grew in central Pennsylvania because the region offered the iron-rich deposits, limestone, water power, and timber needed for iron manufacture in those days.

Later, use of coal allowed the iron industry to focus in a few places such as Pittsburgh, but the iron-making of the Juniata Valley was done in widely scattered furnaces fueled by charcoal. The making of the charcoal is a fascinating chapter in history, oddly romantic now but decidedly not romantic to the people who did it.

A single iron furnace needed about six hundred bushels of charcoal per day to operate.⁷ As many as one hundred men and boys worked, mainly in the autumn and winter, to cut the wood for the charcoal. Wood was cut into four-foot lengths, and anything thicker than about six inches had to be split to make the conversion to charcoal work better. The four-foot-long logs (just over one meter) were stacked four feet high in eight-foot-long cords; a good cutter could supply three of these cords

a single day.

Figure 3.3 Preparing for charcoaling, June 1942, Wayne National Forest, Ohio. C. A. Masie (left) and David Daniels putting wet leaves and then dirt over the wood to restrict oxygen so that burning will produce charcoal. An immense amount of wood was used to make charcoal.

After a winter of cutting, the colliers took over, doing the “coaling” to make charcoal during dry times in spring and summer. An experienced collier and assistants would set up a camp on a flat, dry spot near the cut wood, and live there for several weeks while tending the coals. Thirty or more cords of wood would be stacked carefully in a “pile” fifteen feet high and twice that wide. This pile was then covered with dirt and sod, but leaving strategically placed holes and a central vent. Then the pile was burned beneath the dirt for up to two weeks. The dirt cover slowed the supply of oxygen, while the holes let in just enough air so that the fire smoldered rather than going out. Such a smoldering fire heated the wood sufficiently to drive off or burn up its water, oxygen, and other volatile materials. The pile shrank as it lost these materials, so workers were forced to walk around on top and pack the soil cover back down, lest the holes get big enough to let in enough oxygen to burn up the valuable charcoal. These workers surely walked carefully, knowing they were one misstep from plunging into the glowing hot pit. Eventually, after enough of the original wood was lost, the holes in the soil cover were blocked completely, the fire slowly went out, and the charcoal—now almost all carbon—was separated, cooled, and hauled by mule cart to the furnace.

A lot of other activities were going on around the furnace as well, including mining the iron ore and the limestone, “flatting” the charcoal so that there were no big chunks to clog the furnace, charging the furnace, blasting air in to raise the temperature high enough to melt out the iron and allow the impurities to combine with the limestone flux, and eventually producing the valuable “pig” of iron and a vaguely attractive blue or green glass slag. Anyone walking near one of the old furnaces today, or kayaking a river downstream of a furnace, is still likely to find pieces of the slag. If you’re a history buff, this is a fascinating corner of our heritage.
