Chapter 1: Introduction and a Look Ahead

1.1 Getting An Overview

1.2 Notation, Terminology And Analytical Aspects

1.3 Direct Methods Of Solution

1.4 Transform Methods

1.5 Solution In Series

1.6 Systems Of Equations

1.7 Qualitative Methods

1.8 Numerical Methods

1.9 Modelling With Differential Equations

FURTHER EXERCISES

Chapter 2: First-order Differential Equations – Methods and Models

- 2.1 Introduction And A Quick Review
- 2.2 Complementary Function Plus Particular Integral
- 2.3 Exact Equations And More Integrating Factors
- 2.4 Transforming An Equation – New From Old
- 2.5 Modelling With First-Order Differential Equations

Chapter 3: First-order Differential Equations – Analysis and Approximation

- 3.1 Introduction - Solution Of A Differential Equation
- 3.2 Existence And Uniqueness For The Linear First-Order Equation
- 3.3 The Peano Existence Theorem
- 3.4 Uniqueness Theorems - The Lipschitz Condition
- 3.5 Higher-Order Equations
- 3.6 Picard's Method
- 3.7 Numerical Methods For First-Order Equations

Chapter 4: Second- and Higher-order Homogenous Linear Differential Equations

- 4.1 Introduction
- 4.2 Linear Second-Order Equations
- 4.3 Linearly Dependent And Independent Functions
- 4.4 Fundamental Solution Sets And The General Solution
- 4.5 Second-Order Linear Homogeneous Equations With Constant Coefficients

FURTHER EXERCISES

Chapter 5: Inhomogeneous Linear Differential Equations

- 5.1 Second-Order Inhomogeneous Equations With Constant Coefficients. Undetermined Coefficients
- 5.2 Variation Of Parameters
- 5.3 Higher-Order Equations – Project
- 5.4 D-Operator Methods
- 5.5 A Note On Numerical Methods For Higher-Order Differential Equations
- 5.6 Modelling With Second-Order Equations – Project

FURTHER EXERCISES

Chapter 6: Laplace Transform Methods for Solving Initial Value Problems

6.1 Introduction

6.2 The Laplace Transform

6.3 Laplace Transforms Of The Elementary Functions

6.4 Properties Of The Laplace Transform

6.5 The Inverse Laplace Transform

6.6 Solution Of Initial Value Problems By Laplace Transform

6.7 The Convolution Theorem

6.8 Heaviside And Dirac Functions'

Chapter 7: Systems of Linear Differential Equations

7.1 Introduction

7.2 An Obvious Approach For Homogeneous Systems

7.3 Solution Of Systems By Diagonalization

7.4 Undetermined Coefficients And Variation Of Parameters For Inhomogeneous Systems

7.5 The Exponential Matrix

7.6 Use Of Laplace Transforms In Solving Initial Value Problems For Systems Of Differential Equations

7.7 D-Operator Methods. Elimination

7.8 Higher-Order Systems

7.9 Mathematical Modelling With Systems Of Differential Equations

Chapter 8: Series Solution of Linear Differential Equations

8.1 Introduction

8.2 Singular Points

8.3 Legendre's Equation – Taylor Series Solution

8.4 Legend Re Polynomials

8.5 Frobenius' Method

8.6 Bessel'S Equation - Project

8.7 More 'Special' Functions

FURTHER EXERCISES

Chapter 9: Special Functions and Orthogonal Expansions

9.1 Why Are 'Special Functions' Special?

9.2 The Fourier Series Expansion

9.3 Sturm-Liouville Systems

9.4 The Legendre Sturm-Liouville System -Project

9.5 Orthogonal Functions With Respect To A Weight Function - Project

FURTHER EXERCISES

Chapter 10: An Introduction to Nonlinear Systems

10.1 Introduction

10.2 Linearization Of Nonlinear Systems. Phase Plane And State Space

10.3 The General Linear Homogeneous Second-Order System - Project

10.4 Putting It All Together - The Linearization Theorem

10.5 The Route To Chaos

Appendix – Chapter Summaries

Answers to Exercises

Series Preface

Professor

Chris D. Collinson

Dr

Johnston Anderson

Mr

Peter Holmes

This series is designed particularly, but not exclusively, for students reading degree programmes based on semester-long modules. Each text will cover the essential core of an area of mathematics and lay the foundation for further study in that area. Some texts may include more material than can be comfortably covered in a single module, the intention there being that the topics to be studied can be selected to meet the needs of the student. Historical contexts, real life situations, and linkages with other areas of mathematics and more advanced topics are included. Traditional worked examples and exercises are augmented by more open-ended exercises and tutorial problems suitable for group work or self-study. Where appropriate, the use of computer packages is encouraged. The first level texts assume only the A-level core curriculum.

Preface

This book describes the theory, solution and application of ordinary differential equations. Depending on the background of the students it is intended to provide ample material for a twenty-four lecture modular course, although the method of presentation is designed to be equally conducive to independent learning. The content may be harmlessly reduced by omitting [Chapter 9](#), which aims to set Fourier series (which students may meet elsewhere at the same level) in the context of differential equations, and/or [Chapter 10](#).

The style of presentation is novel, and is intended to engage the reader at crucial points. The problems within the text are exercises designed to lead the reader into the subsequent text - it prepares them for what is to come. Some of these are quite simple, while others form substantial pieces of work which the impatient reader may avoid by continuing with the text. I refer to this approach as 'ask an answer' (a question leads you into the answer, encouraging you to discover the ideas for yourself if you wish) as opposed to 'tell and test' (we tell you in the text, then test what you have learnt in the exercises).

Most sections have reinforcement exercises, and all chapters but the last have end-of-chapter exercises. These include essay type questions, which exercise your appreciation and understanding of the material. These may also provide small group discussion topics. Also you are encouraged to write your own 'verbal' summary of each chapter, as concisely as possible, and compare your result with the Appendix. Writing such summaries is surprisingly instructive, and provides you with an overview of the topic of the chapter, and the interrelations between its components. While answers to most exercises are included, you are encouraged to verify your answers for yourself where possible. This develops confidence and provides plenty of exercise in manipulative skills.

Some sections, and exercises, are 'projects'. These give you the opportunity to develop material for yourself, by reference to other books such as those in the bibliography, or by your own work. Such material is optional and provides opportunities for the enthusiastic reader to delve deeper.

Lastly, I have tried to make the material enjoyable. That doesn't mean it will always be easy!

Bill Cox, *September 1995*

Acknowledgements

My warm thanks to Barry Martin and Chris Collinson for careful reading of the manuscript and many helpful comments. Also many thanks to Val Tyas for her forbearance in word-processing the manuscript through many iterations (this is **definitely** the last one), and Graham Smith for the diagrams. Any remaining errors are entirely mine, of course.

Bill Cox, *Computer Science and Applied Mathematics, Aston University*

Introduction and a Look Ahead

1.1 Getting an overview

Coming to a new mathematics topic such as differential equations is like entering a new land covered with forests of details, conceptual peaks, rivers and highways of understanding, exquisite hidden valleys of interest, and broad featureless plains of monotony. There are various ways you can explore a new land: a guided tour with an expert; a ‘follow the colour coded signposts’ forest walk; a leisurely cruise along the main highways, taking in the sights; live there for a while, wandering through the highways and byways, climbing the peaks by different routes. But however you do it, before you delve into the guide book, you will greatly benefit from a preliminary study of the atlas, to get your bearings. The problem with this geographical analogy is that whilst we are already familiar with the geographical and topographical terminology needed to describe the features of a new land, this is rarely the case in a new mathematics topic – it is doubly difficult to distinguish the wood from the trees if you don’t know what either looks like! However, with some imagination we can lay out the broad features of a new topic using already familiar ideas – and that’s what we will do in this chapter, relying only on very elementary knowledge of calculus and differential equations.

The study of differential equations can be split into a number of broad areas

- Notation and terminology
 - What is the order of a differential equation?
 - What is a ‘solution’ to a differential equation?
- Analytical aspects
 - Existence theorems – under what conditions does a solution exist?
 - Uniqueness theorems – when is a solution unique?
- Methods of solution
 - Range of techniques and their applicability. Exact and approximate methods.
- Applications
 - Constructing and solving models with differential equations.

Depending on your interests, some of these areas may be more relevant than others to you. For example the student of pure mathematics might reasonably be expected to use and prove an existence theorem for a particular class of equations. An engineer on the other hand might be more interested in solution methods (particularly numerical methods).

The remaining sections of this chapter enable you to develop an overview of the subject matter and the structure of the rest of the book, whatever your interests. The individual chapters will give the details and provide opportunity to hone the skills which you need.

1.2 Notation, terminology and analytical aspects

Before we can start to discuss differential equations there is a certain amount of notation and terminology to deal with. The **order** and **degree** of ordinary differential equations are used to classifi

equations, usually for the purposes of analysing or solving them, There is a major division between **linear** and **nonlinear** equations. With a few simple exceptions, nonlinear equations are impossible to solve except by approximate or numerical methods. Analytical questions such as existence and uniqueness are similarly difficult to address for nonlinear equations. However, a great deal may be learnt about nonlinear equations by limiting our ambitions and looking at general **qualitative** behaviour of solutions. Such qualitative methods, which rely heavily on differential geometry, are briefly discussed in [Chapter 10](#). For the most part the rest of this book is concerned with linear equations.

There is a large amount of theoretical knowledge relating to linear equations, as well as many different solution methods. Perhaps the central idea is that of the principle of superposition of solutions, which enables us to construct further solutions of linear equations from linear combinations of known solutions. Another powerful general principle is the construction of the general solution of an inhomogeneous ordinary differential equation from the general solution of the associated homogeneous equation and a particular solution of the inhomogeneous equation ('complementary function' + 'particular integral'). This is a general principle applicable to all inhomogeneous linear equations, not just differential equations, and is a fundamental result in the theory of linear transformations. These, and other, general principles are important both at the theoretical and the practical level. Thus, the split into 'complementary function' and 'particular integral' often reduces the solution of an inhomogeneous equation to little more than guesswork.

By 'analytical aspects' we mean such questions as existence and uniqueness theorems – the 'pure mathematical analysis', as opposed to the specific methods or techniques of solution. Existence and uniqueness theorems abound for linear equations. Such theorems tell us the conditions under which a particular type of differential equation actually has a solution, and to what extent it is unique. The analytical aspects of ordinary differential equations are sometimes regarded as not 'practical', or rather peripheral 'abstract' mathematics. Nothing could be further from the truth. An existence theorem can at least tell you whether it is worth your while looking for a solution to a given differential equation. A uniqueness theorem can tell you under what conditions a solution, once found, is the **only** solution. This means that you can guess a solution (and you may be surprised how much logical 'deductive' mathematics is in fact educated guesswork), safe in the knowledge that if you can verify that it is a solution then it must be **the** solution.

1.3 Direct methods of solution

Large oaks from little acorns grow.

PROBLEM 1

Solve this acorn

$$y' = \lambda y \quad y > 0 \tag{1.1}$$

If the solution is not already second nature to you, then you probably used separation of variables

$$\int \frac{dy}{y} = \lambda \int dx$$

So

$$\ln y = \lambda x + A \quad A \text{ arbitrary}$$

is an **implicit** form of the general solution, which may be written **explicitly** as

$$y = Ce^{\lambda x} \quad C = e^A$$

Of course, not all first-order equations can be solved in this way. For example the general first-order linear equation

$$y' = P(x)y + Q(x)$$

cannot be solved immediately by separation of variables – but it can be integrated directly using an integrating factor which is found by separation of variables. The general message here is that new equations can often be solved by rearranging them in order to take advantage of ones you have already solved.

Back to the acorn. The linear second-order equation

$$y'' - 3y' + 2y = 0$$

really only differs from (1.1) by a second derivative term. But one derivative of an exponential function looks pretty much like another so maybe a solution like $y = e^{\lambda x}$ will work again.

PROBLEM 2

Try a function of the form $y = e^{\lambda x}$ in this second-order equation and find the values of λ for which this is a solution. Write down the most general form of the solution stating the principle you have used. How do you know that the resulting solution obtained by such guesswork is the general solution – how do we know there are not others lurking about, unknown to us?

Substituting $y = e^{\lambda x}$ in the equation gives

$$(\lambda^2 - 3\lambda + 2)e^{\lambda x} = 0$$

This can only be an identity, true for all values of x , if

$$\lambda^2 - 3\lambda + 2 = 0$$

i.e. λ can be 1 or 2.

So two possible solutions are $y = e^x, e^{2x}$. Since the equation is linear and homogeneous, any linear combination of these solutions is also a solution, allowing us to construct a solution of the form

$$y = Ae^x + Be^{2x}$$

where A and B are arbitrary constants. The occurrence of two arbitrary constants in this solution might suggest to us that it is the general solution – but we would need an appropriate existence and uniqueness theorem for second-order linear equations to confirm this for us.

This short plausible treatment (referred to as ‘heuristic’), with which you may be familiar, actually conceals a tremendous amount of theoretical assumption and background – the linear superposition, the treatment of e^x, e^{2x} as somehow independent functions, and finally the implicit use of a **uniqueness theorem** to assure us that the final form of the solution, containing two arbitrary constants, is the unique solution. But all that really concerns us here is that the acorn has sprouted shoots already, enabling us to deal with second- and indeed higher-order linear homogeneous equations.

But what about inhomogeneous equations like

$$y' - y = x + 1?$$

You might already be able to solve this by an integrating factor, obtaining

$$y = Ce^x - (x + 2)$$

with C an arbitrary constant.

But let’s anticipate a general result, which you may have met in the context of second-order equations, and at the same time take advantage of [Problem 1](#). Assume, as we will prove in [Section 2.2](#), that the general solution of such an inhomogeneous equation is the sum of the general solution (**complementary function**) of the homogeneous equation

$$y' - y = 0$$

and a particular solution (**particular integral**) of the full inhomogeneous equation. [Problem 1](#) gives us the complementary function

$$y_c = Ce^x$$

so we only have to find a particular solution. The acorn helps here too, in that it has alerted us to the possibilities of **guessing** a solution (mathematicians make such guesswork

respectable by expressions such as ‘by inspection’, ‘choosing an *ansatz*’ etc., but they all amount basically to inspired guesswork). Maybe we can guess a particular integral. Perhaps something like the right-hand side will work?

PROBLEM 3

Try substituting $y_p = Lx + M$ in the equation, where L and M are constants, and choose L, M to yield a solution.

We find

$$L - (Lx + M) \equiv x + 1$$

from which $L = -1, M = -2$, so

$$y_p = -(x + 2)$$

is the desired particular integral. The general solution is thus

$$y = y_c + y_p = Ce^x - (x + 2)$$

as found by the integrating factor method.

The lesson to learn here is – to find a particular solution to an inhomogeneous equation try a solution of similar form to the right-hand side, although this will not always work. All this, and a lot more to come, we owe to playful extrapolation from the acorn. But also note that we have again used a definite notion of a solution of a differential equation (resulting in the identity from which L and M are determined), and also relied on a uniqueness theorem to reassure us that the solution obtained by guesswork is indeed the solution.

EXERCISES ON 1.3

1. Solve the equation

$$xy' = (3x - 1)y \quad x \neq 0$$

by putting $z = xy$.

2. Solve the equation

$$y'' - 5y' + 6y = 0$$

and check your answer by substituting into the equation.

1.4 Transform methods

We can already see the importance of the exponential function in linear differential equations. You almost wonder if we could somehow change the function $y(x)$, by some sort of exponential transformation, to a new function which simplifies the whole business of dealing with differential equations. One way of transforming functions such as $y(x)$ is by an **integral transform** and, given the importance of the exponential function, it is perhaps no surprise that a transform of the form

$$\mathcal{L}[y(x)] = \tilde{y}(s) = \int_0^{\infty} e^{-sx} y(x) dx \quad s > 0$$

does prove useful in differential equations. This is in fact the **Laplace transform**, which we study in detail in [Chapter 6](#).

PROBLEM 4

Prove that $\mathcal{L}[y'] = s\tilde{y}(s) - y(0)$.

We have, from the above definition,

$$\begin{aligned} \mathcal{L}[y'] &= \int_0^{\infty} e^{-sx} \frac{dy(x)}{dx} dx \\ &= [y(x)e^{-sx}]_0^{\infty} + s \int_0^{\infty} e^{-sx} y(x) dx \\ &= -y(0) + s\tilde{y}(s) \end{aligned}$$

on integrating by parts and simplifying the ‘boundary term’. (We will fill in the details in [Chapter 6](#).)

The point is that this transform converts the derivative to simple multiplication by s – and automatically incorporates the initial value $y(0)$, i.e. it reduces a problem in calculus to one in algebra. This suggests it may be useful in the solution of initial value problems in which y is specified at $x = 0$. Let’s see how it deals with the acorn.

PROBLEM 5

Solve the initial value problem

$$y' = y \quad y(0) = 1$$

by taking the Laplace transform of the equation.

We have

$$\mathcal{L}[y' - y] = \mathcal{L}[y'] - \mathcal{L}[y] = s\tilde{y}(s) - y(0) - \tilde{y}(s) = \mathcal{L}[0] = 0$$

So

$$(s - 1)\tilde{y}(s) = y(0) = 1 \quad \tilde{y}(s) = \frac{1}{s - 1} .$$

Thus the solution $y(x)$ has Laplace transform $\tilde{y}(s) = 1 / (s - 1)$. As you will see in [Chapter 6](#) this yields

$$y(x) = e^x$$

In this case the Laplace transform looks like a sledgehammer to crack an acorn, but in more complicated initial value problems the Laplace transform is a powerful tool and cracks much harder nuts.

EXERCISE ON 1.4

Solve the initial value problem

$$y' = y + 1 \quad y(0) = 1$$

by Laplace transform. *Hint.* Find the Laplace transform of 1. Split $\tilde{y}(s)$ into partial fractions.

1.5 Solution in series

(1.1) has already produced a sizeable tree – but surely we have exhausted the theme – there must be differential equations not owing something to such a simple equation? What about

$$(1 - x^2)y'' - 2xy' + 2y = 0$$

which is linear, but has non-constant coefficients? It is the **Legendre equation**, which we study in [Chapter 8](#). We are not going to solve it here, but we can use the acorn to get an insight into how we can solve it. The key lies in what we understand by the function e^x . If I asked you for a definition of e^x , I suspect you would give its series definition

$$e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \dots$$

This suggests yet another way to solve the acorn.

PROBLEM 6

Solve (1.1) by assuming a power series solution of the form $y = a_0 + a_1x + a_2x^2 + \dots$. We have

$$y' = a_1 + 2a_2x + 3a_3x^2 + \dots = y = a_0 + a_1x + a_2x^2 + \dots$$

Since this must be true for all values of x we find, by equating coefficients of like powers of x , that

$$na_n = a_{n-1} \quad n = 1, 2, 3, \dots$$

Solving this recurrence relation gives

$$a_n = \frac{a_0}{n!}$$

so a solution of the differential equation is

$$y(x) = a_0 \left(1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \dots \right) = a_0 e^x$$

where a_0 is arbitrary. Clearly, this method can be applied to many other types of equation to obtain series solutions, including the Legendre equation given above. It is merely fortuitous that in the case of the acorn we actually know that the series represents the function e^x . We now have another method for solving differential equations – the **series solution** method – to which [Chapter 8](#) is devoted.

EXERCISE ON 1.5

Assume a power series solution for the equation

$$(1 - x)y' - y = 0 \quad |x| < 1$$

and show that the coefficients, a_n , satisfy $a_n = a_{n-1}$. Why is the condition $|x| \leq 1$ specified?

Deduce the general solution and compare with the result obtained by separation of variables.

1.6 Systems of equations

What about systems of equations? Consider the system

$$y'_1 = 2y_1 - 3y_2 \quad y'_2 = y_1 - 2y_2$$

Write it in matrix form

$$\mathbf{y}' = A\mathbf{y}$$

where

$$A = \begin{bmatrix} 2 & -3 \\ 1 & -2 \end{bmatrix} \quad \mathbf{y} = \begin{bmatrix} y_1 \\ y_2 \end{bmatrix}$$

Looks familiar? Would you be surprised to learn that the solution of this **matrix differential equation** can be written

$$\mathbf{y} = e^{Ax} \mathbf{C}$$

where \mathbf{C} is a constant 2×1 vector, and e^{Ax} is the matrix exponential function defined by

$$e^{Ax} = I + Ax + \frac{A^2 x^2}{2!} + \frac{A^3 x^3}{3!} + \dots$$

where I is the 2×2 unit matrix? We study such systems of equations in [Chapter 7](#).

There is also another way of dealing with this system if you know a little matrix theory. Consider the matrix

$$U = \begin{bmatrix} 3 & 1 \\ 1 & 1 \end{bmatrix}$$

PROBLEM 7

Show that the columns of U are the eigenvectors of A .

Show that

$$U^{-1}AU = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \equiv D$$

Rewrite the matrix differential equation for y in the form

$$\frac{d(U^{-1}y)}{dx} \equiv \frac{dY}{dx} = U^{-1}AUU^{-1}y \equiv DY$$

to obtain the system

$$Y'_1 = Y_1 \quad Y'_2 = -Y_2$$

i.e. two acorns!

This method is the **diagonalization** method, which essentially diagonalizes the coefficient matrix to decouple the system of differential equations and reduce it to a simpler system. It may be applied to any number of linear equations, and also to inhomogeneous systems.

EXERCISE ON 1.6

Solve the equations obtained for Y_1 , Y_2 and hence obtain expressions for the solutions y_1 , y_2 for the original system of this section.

1.7 Qualitative methods

Suppose we couldn't solve the acorn – that is, there was no simple function like $y = e^x$ which satisfied it. Then we can still say quite a lot about the solution simply by studying the differential equation itself.

First, note that multiplying (1.1) through by an arbitrary constant:

$$C \frac{dy}{dx} = \frac{d(Cy)}{dx} = Cy$$

show that if y is a solution then so is Cy . Intuitively, we feel that the form of the solution curve $y = y(x)$ should be fixed once we specify an initial point through which it passes. Indeed, since repeated differentiation of the equation will furnish us with all required derivatives, once such an initial point is specified, we can see that we could generate the Taylor series for the solution $y = y(x)$ near to $x = 0$. Since, therefore, the solution is (at least locally) determined by the single initial condition, we expect the general solution $y = y(x)$ to contain one arbitrary parameter only. We have seen above that if y is a solution, so is Cy with C arbitrary, and so the solution can be written in the form

$$y = Cf(x)$$

where, from what we have said above, $f(x)$ must be a function of x only, containing no further arbitrary constants. It also tells us that if y is a solution then so is $-y$. The solution curves are therefore symmetric about the x -axis and we can confine ourselves to $y > 0$.

Next, note that the gradient of any solution curve at the point (x, y) is always equal to y for all values of x . In particular, as y gets smaller, the slope of the curve does too, and as y increases, so does the slope of the curve. This tells us that for $y > 0$ any solution curve is monotonic increasing, and has no turning points. If we were to plot the field of gradients of solution curves from the differential equation, then it would soon become clear that the solution curves have an exponential form. All this is apparent without actually solving the equation.

EXERCISE ON 1.7

Plot the gradient field for (1.1) at selected points and by connecting these by eye construct a sketch of the solution to the initial value problem.

$$y' = y \quad y(0) = 1$$

up to $x = 2$. Your sketch should, of course, approximate to the e_x curve.

1.8 Numerical methods

Qualitative methods can give useful information about the solutions of differential equations even when we cannot solve them exactly. More detailed information about solutions may be found by numerical methods of a number of different types. The gradient field qualitative approach of the previous section can be refined into such a method. Essentially, one starts from a fixed point on a particular solution curve and uses the gradient, calculated from dy/dx via the differential equation, to take us to a neighbouring point near the solution curve. The process is then repeated. Again, (1.1) provides a simple example of this. Thus, suppose we wish to solve the initial value problem

$$y' = y \quad y(0) = 1 .$$

PROBLEM 8

Starting from $x = 0$, obtain an approximation for $y(0.1)$ by approximating the slope of the tangent to the solution curve at $x = 0$ by

$$\frac{y(0.1) - y(0)}{0.1 - 0}$$

This is approximately equal to dy/dx at $x = 0$, which is given, from the differential equation, by $y(0) = 1$. So

$$\frac{y(0.1) - y(0)}{0.1} \simeq y(0) = 1$$

$$y(0.1) \simeq y(0) + 0.1y(0) \simeq 1 + 0.1 = 1.1$$

Thus, an approximation to the solution of the initial value problem at $x = 0.1$ is 1.1. The actual value is $e^{0.1} \cong 1.1052$, so our approximation is not bad.

PROBLEM 9

Now repeat the process starting from $x = 0.1$, using the approximation for $y(0.1)$ found above, to obtain an approximation for $y(0.2)$

We have

$$\frac{y(0.2) - y(0.1)}{0.2 - 0.1} \simeq \frac{dy}{dx}(0.1) = y(0.1) \simeq 1.1$$

So

$$y(0.2) \simeq y(0.1) + 0.1y(0.1) \simeq 1.1 + 0.1 \times 1.1 = 1.21$$

Thus an approximation to $y(0.2)$ is 1.21. The correct value is $e^{0.2} \cong 1.2214$. Again, not bad.

PROBLEM 10

Repeat this process to get approximations to the solution for $x = 0.3, 0.4, 0.5$,
